# Optimal Political Districting: The Anchor Method 

Wes Gurnee<br>MIT ORC<br>wesg@mit.edu

#### Abstract

We study the problem of optimal political redistricting. That is, the problem of splitting up a state's voting precincts in to $k$ population balanced and continuous regions that are optimal with respect to one or more objectives, typically involving political (un)fairness. We present a novel formulation, based on the modeling idea of an anchor, which enables us to solve real scale problems with some convergence guarantees.

## 1 Overview

The political districting problem (PDP) is the decision problem of splitting $n$ precincts into $k$ contiguous and population balanced districts. In the United States, the districts of the House of Representatives are redrawn every 10 years following the decennial census and reapportionment. Given the outsized influence that district composition has on electoral outcomes, how districts are drawn and who draws them, is an extremely contentious (read: litigious) matter. While most districts are drawn by partisan officials with political motives, optimization algorithms offer a more objective and less biased alternative to redistricting.

The most natural MIP formulations for political redistricting resemble a facility location problem: $n$ binary variables for each precinct indicating whether to "open a district" at this location (with supply equal to the prescribed district population), and an additional $n^{2}$ binary decision variables indicating whether or not precinct $j$ is apart of the district centered on precinct $i$ (i.e., each precinct has a demand equal to its population, and can only be served by one facility). Unfortunately, these $n^{2}$ formulation do not scale to real world problems with $O\left(10^{5}\right)$ precincts, both due to the high number of variables, and the higher number of constraints required to enforce contiguity $O\left(k n^{2}\right)$. Furthermore, decomposition algorithms do not work well in this setting due to the massive degeneracy of the primal problem. These challenges necessitate a different approach.
One of the original solution techniques for the PDP proposed by [1] adopted a heuristic similar to Lloyd's algorithm for $k$-means: fix the centers $y$, optimize $x$, update $y$ to be the new centroids, and iterate until convergence. However, this approach did not explicitly enforce contiguity and only optimized for compactness. We propose a modernized formulation capable of incorporating the full range of legal constraints. A key part of our approach is based on a generalization of the center block, which we call an anchor. The purpose of an anchor is to break symmetry and act as the source node for the flow variables which enforce contiguity. The critical difference, however, is that we can define an anchor invariant formulation such that for the optimal districting, any choice of anchors (that is, any choice of precincts in disjoint districts) will yield the same optimal plan. Conceptually, the anchors implicitly define the feasible space, but by construction, can be decoupled from the objective value. This feature is what makes it possible to create optimality guarantees.

## 2 Formulation

In this section, we will assume a set of anchors are given, and describe the inner loop formulation. Our integer programming model is given below where $N$ is the set of blocks, $A \subset N$ is the set of anchors, and $E$ is the edge set of the adjacency graph. The main decision variables are $x_{i j}$ indicating if precinct $j$ is assigned to district (anchor) $i$. We enforce that the assignment is a strict partition of precincts (2), are population balanced (3) and contiguous (4-6). We implement contiguity with flow variables $f_{i j k}$ indicating the flow from anchor $i$ that traverses the arc between adjacent
precincts $j$ and $k$, and require that all precincts demand one unit of flow of type $i$ if assigned to the anchor $i$.

$$
\begin{array}{lrl}
\text { min } & f(x) & \\
\text { s.t. } & \sum_{i \in A} x_{i j}=1 & \forall j \in N \\
& 1-\epsilon \leq \sum_{j \in N} x_{i j} \hat{p}_{j} \leq 1+\epsilon & \forall i \in A \\
& \sum_{k \in \delta(j)}\left(f_{i k j}-f_{i j k}\right)=x_{i j} & \forall i \in A, j \in N \\
& \sum_{k \in \delta(j)} f_{i k j} \leq M x_{i j} & \forall i \in A, j \in N \\
& \sum_{j \in \delta(i)} f_{i j i}=0 & \forall i \in A,(j, k) \in E
\end{array}
$$

where $\hat{p}_{j}$ is the population of block $j$ divided by the ideal district population, and $\delta(i)$ is the set of blocks adjacent to $i$. We leave a generic objective $f(x)$ for now, as the hardest part of the PDP is in efficiently enforcing feasibility. An advantage of this formulation is that it is flexible in accommodating additional modeling logic (i.e., there is no special structure we must be careful to preserve). In the next section, we describe many such extensions relevant to redistricting, that will serve as terms in our objective or satisfy legal criteria specific to certain states.

### 2.1 Extensions

Compactness For many reasons-legal, aesthetic, normative-it is common to either constrain or optimize for compactness. Here we describe how to incorporate three different notions of compactness: dispersion, flow distance, and edge cuts/perimeter.
(Dispersion)

$$
\begin{equation*}
\sum d_{i j}^{\alpha} x_{i j} \tag{9}
\end{equation*}
$$

Dispersion, sometimes also called moment or inertia when $\alpha=2$, is a compactness metric parameterized by $\alpha$ and seeks to minimize the $l_{\alpha}$ distance of the assignment.
(Flow distance)

$$
\begin{equation*}
\sum w_{i j k} f_{i j k} \tag{10}
\end{equation*}
$$

The flow distance metric is much less common, but we noticed that it was very efficient to optimize, because it broke the symmetry implicit in the flow variables. That is, under this objective, not all flow paths from $i$ to $j$ are of equal cost, and hence the resulting flow structure will favor compact spanning trees.
(Cut Edges)

$$
\begin{equation*}
u_{j k} \geq x_{i j}-x_{i k} \tag{11}
\end{equation*}
$$

$$
\forall i \in A,(j, k) \in E
$$

Lastly, the edge cut formulation is an appealing graph theoretic measure of compactness, as it is scale agnostic, unlike the dispersion metric. To implement it, we introduce binary variables $u_{j k}$ for each edge which gets set to 1 whenever $x_{i j}$ and $x_{i k}$ are different, that is, when blocks $j$ and $k$ are assigned to different districts. We can also add a weight $w_{j k}$ when summing the edge cuts to get the interior perimeter of the districting plan, which penalizes cutting edges with long shared borders (this favors aesthetically pleasing districts with clean borders). Another advantage of this measure is that it is anchor invariant, which we will explain further in Section 3.
Despite all of these advantages, this linear relaxation of the edge cut formulation is terrible. The optimal solution will set $x_{i j}=\frac{1}{k}$ to make all edge differences 0 . We found it was intractable to optimize for all but the smallest synthetic networks using this objective.

Political Objectives Of course the main set of objectives in political redistricting are political. For simplicity, we consider two-party election results where $v_{j}$ gives the Republican vote share for block $j$. Then if $\hat{v_{j}}=\hat{p_{j}} v_{j}$, we introduce vote share variables $r_{i}$ and seat share variables $\psi_{i}$

$$
\begin{equation*}
r_{i}=x_{i}^{T} \hat{v} \tag{12}
\end{equation*}
$$

$$
\forall i \in A
$$

$$
\begin{equation*}
\psi_{i}=\sigma_{P W L}\left(r_{i}\right) \quad \forall i \in A \tag{13}
\end{equation*}
$$

to model the expected political outcomes of a district plan. Here $\sigma_{P W L}$ is a piecewise linear approximation of the cumulative density function corresponding to the probability that a seat is occupied by a Republican, given the vote share $r_{i}$. Since there are only $k \ll n$ of these variables, it is feasible to introduce this more elaborate modeling logic. We note one significant drawback with this approach is the implicit assumption of uniform turnout, to avoid introducing a fractional formulation.
With these political estimates, we can optimize for different measures of partisan fairness. The most basic measure is the degree to which the overall expected seat share deviates from some ideal seat share $h^{*}(v)$.

> (Partisan Fairness)

$$
\min \left|\sum_{i} \psi_{i}-h^{*}(v)\right|
$$

For pure proportionality, we would let $h^{*}(v)=1$. We note that it is more straightforward to gerrymander than to optimize for fairness, as partisan advantage can be optimized by simply minimizing or maximizing the sum of $\psi_{i}$. Another example objective which would be straightforward to implement is maximizing the number of competitive seats. We can measure competitiveness as the distance of $r_{i}$ from being 50-50, discounted by $\alpha$ :
(Competitiveness)

$$
\begin{equation*}
\max \sum_{i} t_{i} ; \quad t_{i} \leq \max \left(1-\alpha\left|0.5-r_{i}\right|, 0\right) \tag{15}
\end{equation*}
$$

Voting Rights Act Another important set of legal constraints are those laid out by the Voting Rights Act (VRA) on providing sufficient opportunities for minority candidates to get elected. These rules are complicated, and are not mathematically precise, but we can approximate them by introducing binary variables $y_{i}^{g}$ to indicate whether or not district $i$ is an opportunity district for group $g$ (though, we could also make these continuous variables corresponding to a probability estimate).

## (VRA Compliance)

$$
\begin{equation*}
y_{i}^{g} \leq \alpha \sum_{j} x_{i j} \hat{p}_{j}^{g} ; \quad \sum_{j} y_{i}^{g} \geq g_{\min } \quad \forall g \tag{16}
\end{equation*}
$$

Then, per the laws and demographics of a state, we enforce that the districting plan meet a minimum level of opportunity for every group.

Boundary Preservation Finally, we consider preservation of existing political subdivisions such as counties, wards, or townships and/or preserving communities of interest (COI). We note that is trivial to add a hard constraint on two or more blocks being together: just merge them in the underlying adjacency graph. However, this can lead to feasibility issues if many of the blocks become merged because the district population tolerances are very strict.
Usually a more practical approach is to again add binary variables indicating whether or not a particular region is kept whole. If also using an edge cut formulation, one can model this by simply checking if any edges in the region $R_{t}$ are cut
(Boundary Preservation I)

$$
\begin{equation*}
s_{t} \geq u_{j k} \quad \forall t, \forall(j, k) \in E \cap C_{t} \tag{17}
\end{equation*}
$$

However, as discussed previously, the linear relaxation of the $u_{j k}$ is too weak to be tractable at large scale. Another modeling alternative is to check if the region is fully contained in district $i$
(Boundary Preservation II)

$$
\begin{equation*}
\left|C_{t}\right|\left(1-s_{i t}\right) \leq \sum_{j \in C_{t}} x_{i j} \tag{18}
\end{equation*}
$$

However, this still uses a big-M formulation (i.e., the linear relaxation still is not tight) and requires $k$ times as many variables.

### 2.2 Alternate Formulations

We also tried a disaggregated flow formulation [2] with flow variables

$$
f_{i j}^{k \ell}= \begin{cases}1 & \text { if edge }(k, \ell) \in E \text { is on the path from anchor } i \text { to block } j \\ 0 & \text { otherwise }\end{cases}
$$

for all $(k, \ell) \in \Delta_{i j}=\left\{(k, \ell) \in E: d_{i k}+d_{\ell j} \leq \alpha d_{i j}\right\}$. That is, we only consider edges such that the distance of the shortest path $i, k, \ell, j$ is no more than a factor $\alpha$ of the shortest path from $i$ to $j$. The constraints are very similar to the aggregated formulation:

$$
\begin{array}{lr}
\sum_{k \in \delta(i)} f_{i j}^{i k}-f_{i j}^{k i}=x_{i j} & \forall i \in A, \forall j \in N \backslash A \\
\sum_{\ell \in \delta(k)} f_{i j}^{k \ell}-f_{i j}^{\ell k}=0 & \forall i \in A, \forall j \in N \backslash A, \forall k \in \Delta_{i j} \backslash A \\
\sum_{k \in \delta(i)} f_{i j}^{k \ell}=0 & \forall i \in A, \forall j \in N \backslash A \\
\sum_{\ell \in \delta(k)} f_{i j}^{\ell k} \leq x_{i k} & \forall i \in A, \forall j \in N \backslash A, \forall k \in \Delta_{i j} \backslash A \\
f_{i j}^{k \ell} \geq 0 . &
\end{array}
$$

While this formulation is tighter given that we remove the big-M constraints, the memory requirements of this formulation are too large for full scale problems. For North Carolina, a medium state with 13 districts and 2183 blocks, the formulation contained 122800365 rows, 143450406 columns, 488095135 nonzero coefficients and took almost an hour just to construct the model (and then promptly crashed due to memory pressure). It is possible that more aggressive variable fixing and clever engineering effort could ameliorate these challenges but we did not pursue this line of inquiry further.

### 2.3 Variable Fixing

To reduce the size of the problem we experimented with variable fixing, that is, setting $x_{i j}=0$ for pairs of anchors and blocks which are unlikely to be feasible let alone optimal. Our first thought was just to set $x_{i j}=0$ if $i$ was not within the $\Gamma$ closest anchors. However, this does not work well for blocks where there is a steep gradient in population density. It may be the case that all of the close anchors are in a large urban area, but in an optimal (or even feasible) plan, these blocks would be assigned to a much more distant rural anchor.
Instead, we leverage the fact that at each iteration we have a feasible plan as a warm start. In particular, we set the bound as

$$
x_{i j} \leq \begin{cases}1 & \text { if block } j \text { is assigned to a district adjacent to district } i \\ 0 & \text { otherwise } .\end{cases}
$$

In other words, we further restrict the blocks to only be assigned to neighboring anchors in the warm start solution. This accommodates for population density gradients and other geographic features that affect the range of feasible assignments. Of course, fixing $x_{i j}$ to 0 also allows fixing $f_{i j k}$ to be 0 for all $k$.

## 3 Anchors

The obvious question we have deferred until now is: how do we choose anchors?
In theory, we would like a routine which uses the faster to solve $O(n k)$ formulation above as a subroutine to find a globally optimal solution. To study convergence, we introduce the concept of an anchor invariant formulation. The defining property of an anchor invariant formulation is that, for a globally optimal districting plan, any choice of anchors such that each district contains exactly one will yield the same optimal solution. In other words, anchors only affect the feasibility of an optimal solution, not the objective value. We note that the base formulation is anchor invariant, and that all of the extensions are anchor invariant with the notable exceptions of dispersion and flow based compactness (i.e., the tractable compactness metrics).
When the number of districts is small, we can do random sampling to obtain a simple probabilistic bound on the number of samples/iterations until optimality. In particular, it is the probability of sampling $k$ elements from a set of $n$ elements (without replacement) that are implicitly partitioned into $k$ sets, where each of the $k$ elements are from different sets:

$$
\begin{equation*}
\prod_{i=0}^{k-1} 1-\frac{(i-1)}{k} \tag{19}
\end{equation*}
$$

assuming each district has exactly $n / k$ blocks. For larger numbers of districts this bound is useless, and we would expect the vast majority of randomly sampled anchor sets to be infeasible. One could likely make this bound substantially

Figure 1: Districting plans optimized under different objective values.
tighter by exploiting the fact that these $k$ sets are spanning trees of the underlying adjacency graph, but that is outside of the scope of this work.
In practice, there might be several natural choices of anchors, such as the home precincts of the incumbents to prevent "hijacking" gerrymanders, the historic center of a district, or the main town or geographic area associated with a district. Again, if we use an anchor invariant formulation, and we condition on no two incumbents being put into the same district (or similar disjoint criterion), then the solution is globally optimal. Of course, the number of districts may change between cycles, or we may not want to preserve incumbency advantages, so we cannot rely on such conditions.

A more general approach is to use a heuristic similar to Lloyd's algorithm for $k$-means. That is, starting from some set (like incumbent home locations, or the centroid of an existing or random plan), we iteratively solve the above MIP, and then use the blocks nearest to the optimized district centroids as the next set of anchors, and continue this iteration until there are no updates. While this only gives locally optimal solutions, we can utilize random restarts to get what are likely globally optimal solutions.

## 4 Results

Given the difficulty of the formulation, it was challenging to perform thorough full-scale experiments. Our main experimental result involve running our algorithm for a few different political and compactness objectives in North Carolina (see Figure 1 We comment on high level findings and attach some of our solver logs in the appendix.
We first create a random plan using a recursive spanning tree algorithm [3]. We then get the first set of anchors by taking the blocks nearest the population weighted centroid of the districts in the initial plan. We then iterate, using our formulation described in Section 2 with a one hour timeout, continuing to update the anchors to be the new centroids until there are no updates in the location of the anchors. We also always use the previous assignment as a warmstart.
We find that optimizing for compactness objectives, especially flow distance, is extremely fast, usually taking no more than a few seconds per iteration while converging in a very small number of iterations. The political objectives, in contrast, always take the full hour and usually timeout with a double digit gap (see Appendix). The solver spends a long time at the root node, generating hundreds or thousands of flow cover cuts in addition to hundreds of mixed-integer round cuts and a mix of all others. Nevertheless, the gerrymandering capabilities are quite impressive (see Figure 2 which also records the anchors and objective value of the iterations). Due to the piecewise-linear nature of the objective, the optimal solution tries to make as many districts as possible have $55 \%$ Republicans (at estimate $95 \%$ probability of victory), and manages to get a full 11/13 districts to about this threshold.

Figure 2: Anchors and objective value when optimizing for expected Republican seat share.

## 5 Conclusions

Our results show the scalability is mixed. We initially expected our algorithm would require $O(10)$ iterations taking each $O(1 \mathrm{~min})$ but it turned out be closer to $O(1)$ iterations taking $O(1 \mathrm{hr})$. Potential ideas for future work include

- More aggressive variable fixing, potentially only add $x_{i j}$ for $j$ in an incident county to district $i$ from the previous iteration.
- Use disaggregated flow formulation but with column generation of flow paths.
- Decay the value of $M$ further away from the anchor.
- Derive valid inequalities to tighten the formulation.
- Gurobi tuning to find better solver parameters.
- Fix the bug which causes the western most district to never change.
